

C++ Basics

**I'M SORRY,
YOU'RE BASIC.**

A black and white line drawing of a woman's head and shoulders. She has short, wavy hair and is smiling slightly. She is holding a clear glass filled with water in her right hand. The drawing is done in a classic, detailed style with cross-hatching for shading.

Announcements

Lab 1 this week!

Homework posted Friday
(will be on gradescope)

Avoid errors

To remove your program of bugs, you should try to test your program on a wide range of inputs

Typically it is useful to start with a small piece of code that works and build up rather than trying to program everything and then debug for hours

Variables

Variables are objects in program

To use variables two things must be done:

- Declaration
- Initialization

See: uninitialized.cpp

Example if you forget to initialize:

I am 0 inches tall.

I am -1094369310 inches tall.

Variables

```
int x, y, z; ← Declaration  
x = 2;      }  
y = 3;      } Initialization  
z = 4;      }
```

Same as:

```
int x=2, y=3, z=4;
```

Variables can be declared anywhere
(preferably at start)

Assignment operator

= is the assignment operator

The object to the right of the equals sign is stored into the object in the left

```
int x, y;
```

```
y = 2;
```

```
x = y+2;
```

See: `assignmentOp.cpp`

Assignment operator

= is NOT a mathematic equals

```
x=3;
```

```
x=4; // computer is happy!
```

This does not mean $3=4$

Assignment operator

To the left of = needs to be a valid object that can store the type of data on the right

```
int x;
```

```
x=2.6; // unhappy, 2.6 is not an integer
```

```
x+2 = 6; // x+2 not an object
```

```
2 = x; // 2 is a constant, cannot store x
```

Assignment operator

What does this code do?

```
int x = 2, y = 3;
```

```
y=x;
```

```
x=y;
```

What was the intention of this code?

Increment operators

What does this code do?

```
int x = 2;  
x=x+1;
```

Increment operators

What does this code do?

```
int x = 2;  
x=x+1;
```

Same as:

```
x+=1;
```

or

```
x++;
```

Increment operators

Two types of increment operators:

`x++;` // increments after command

VS

`++x;` // increments before command

Complex assignments

The following format is general for common operations:

variable (operator)= expression

variable = variable (operator) expression

Examples:

$x += 2$

$x *= y + 2$

$x = x + 2$

$x = x * (y + 2)$

Order of operations

Order of precedence (higher operations first):

-, +, ++, -- and ! (unary operators)

*, / and % (binary operators)

+ and - (binary operators)

% is remainder operator

(example later in simpleDivision.cpp)

Order of operations

Binary operators need two arguments

Examples:

$2+3$, $5/2$ and $6\%2$

Unary operators require only one argument:

Examples: (see `binaryVsUnaryOps.cpp`)

$+x$, $x++$, $!x$

($!$ is the logical inversion operator for `bool`)

Identifiers

HELLO

my name is

*Inigo Montoya
You killed my Father
Prepare to die*

Identifiers

An identifier is the name of a variable (or object, class, method, etc.)

`int sum;`

type

identifier

- Case sensitive
- Must use only letters, numbers or _
- Cannot start with a number
- (Some reserved identifiers, like main)

Identifiers

Already did this in week 1!
See: RuntimeError.cpp

```
1 #include <iostream>
2 using namespace std;
3
4 int main()
5 {
6     int number;
7
8     cout << "What is your lucky number?" << endl;
9     cin >> number;
10    cout << "I like " << 10/number << "!\\n";
11
12    return 0;
13 }
14
```

Identifiers

Which identifiers are valid?

1) james parker

2) BoByBoY

3) x3

4) 3x

5) x_____

6) _____x

7) Home.Class

8) Five%

9) x-1

Identifiers

Which identifiers are valid?

~~1) james parker~~

2) BoByBoY

3) x3

~~4) 3x~~

5) x_____

6) _____x

~~7) Home.Class~~

~~8) Five%~~

~~9) x 1~~

Identifiers

(See: float.cpp)

```
7 int main()
8 {
9     float Float, fLoat, fl0at, FLOAt, FLOAT;
10    Float = 1;
11    fLoat = 2;
12    fl0at = -3;
13    FLOAT = 2;
14    FLOAt = 4;
15    cout << (-fLoat + floAT(fLoat*fLoat - FLOAt * Float * fl0at))/(FLOAT*Fl
16    cout << (-fLoat - floAT(fLoat*fLoat - FLOAt * Float * fl0at))/(FLOAT*Fl
17
18    return 0;
19 }
```

Identifiers

Types

There are only 10 types
of people in this world;
those who understand binary
and those who don't.

Variables

We (hopefully) know that if you say:

```
int x;
```

You ask the computer for a variable called *x*

Each variable actually has an associated type describing what information it holds (i.e. what can you put in the box, how big is it, etc.)

Fundamental Types

`bool` - true or false

`char` - (character) A letter or number

`int` - (integer) Whole numbers

`long` - (long integers) Larger whole numbers

`float` - Decimal numbers

`double` - Larger decimal numbers

See: `intVSlong.cpp`

int vs long?

int - Whole numbers in the approximate range:
-2.14 billion to 2.14 billions (10^9)

long - Whole numbers in the approximate range:
-9.22 quintillion to 9.22 quintillion (10^{18})

Using **int** is standard (unless you really need more space, for example scientific computing)

float vs double?

float vs double?

`float` is now pretty much obsolete.

`double` takes twice as much space in the computer and 1) has wider range and 2) is more precise

Bottom line: use `double` (unless for a joke)

float and double

Both stored in scientific notation

```
double x = 2858291;
```

Computer's perspective:

$$x = 2.858291e6$$

or

$$x = 2.858291 * 10^6$$

Welcome to binary

Decimal:

$$1/2 = 0.5$$

$$1/3 = 0.33333333$$

$$1/10 = 0.1$$

Binary:

$$0.1$$

$$0.0101010101$$

$$0.0001100110011$$

double is often just an approximation!

Numerical analysis

Field of study for (reducing) computer error

See: `subtractionError.cpp`

Can happen frequently when solving system of linear equations

bool

You can use integers to represent `bool` also.

`false` = 0

`true` = anything else

(You probably won't need to do this)

int or double?

If you are counting something (money),
use `int`

If you are dealing with abstract concepts (physics),
use `double`

`int` doesn't make “rounding” mistakes

Primitive type hierarchy

`bool < int < long < float < double`

If multiple primitive types are mixed together in a statement, it will convert to the largest type present

Otherwise it will not convert type

Primitive type hierarchy

```
int x;  
double y;
```

$x+y$

Converted to
double

```
int x;  
int y;
```

x/y

Not converted
(still int)

Integer division

See: simpleDivision.cpp

Can be fixed by making one a double:

$1/2.0$

or

`static_cast<double>(1)/2`

Constants

You can also make a “constant” by adding `const` before the type

This will only let you set the value once

```
const double myPI = 3.14;  
myPI = 7.23; // unhappy computer!
```

Functions

Functions allow you to reuse pieces of code (either your own or someone else's)

Every function has a return type, specifically the type of object returned

`sqrt(2)` returns a double, as the number will probably have a fractional part

The “2” is an argument to the `sqrt` function

Functions

Functions can return **void**, to imply they return nothing (you should not use this in an assignment operation)

The return type is found right before the functions name/identifier.

int main() { ... means main returns an **int** type, which is why we always write **return 0** and not **return 'a'** (there is no char main())

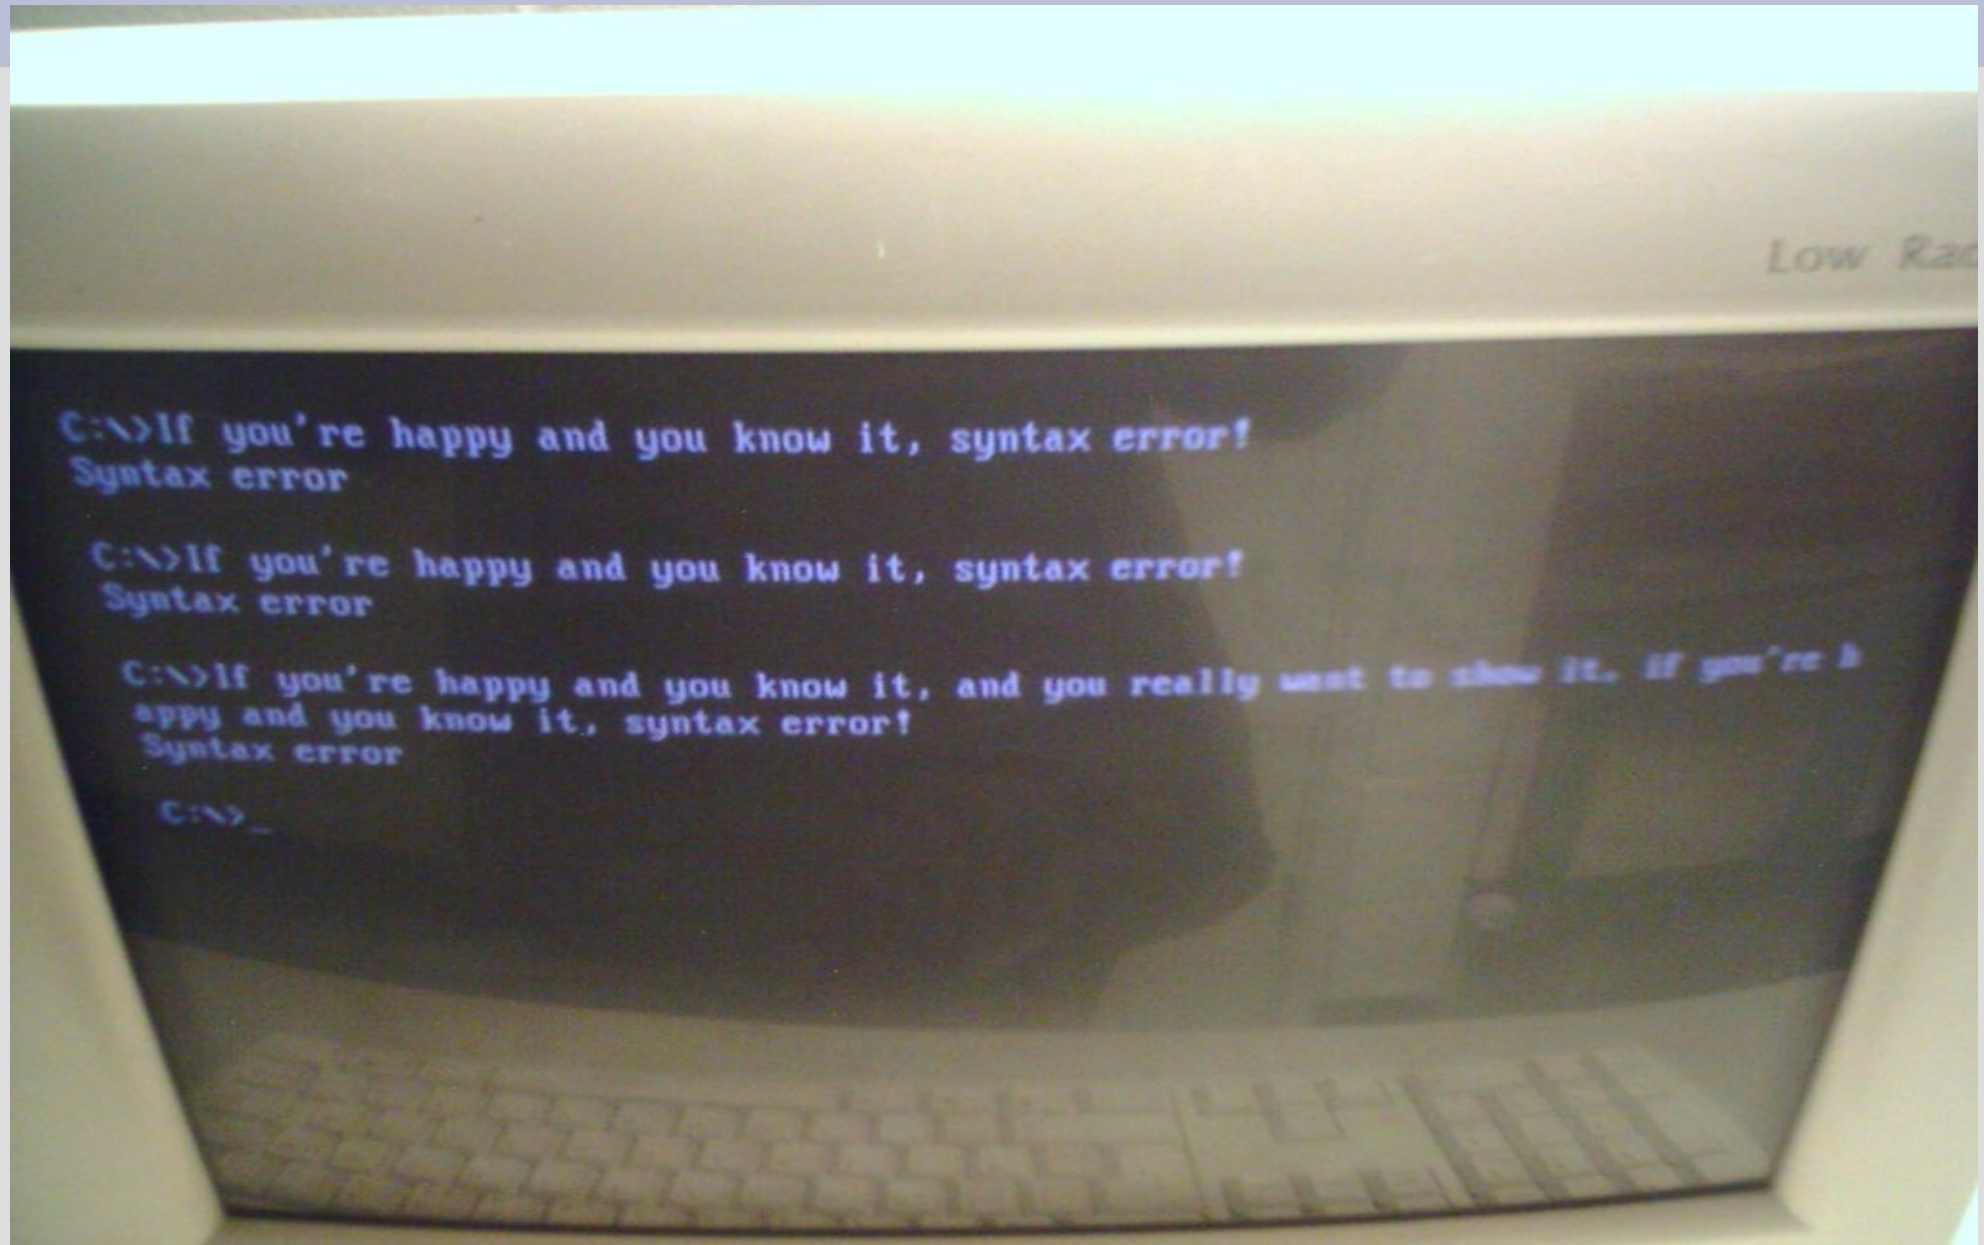

Functions

A wide range of math functions are inside `<cmath>` (get it by `#include <cmath>`; at top)

We can use these functions to compute Snell's Law for refraction angle

(See: `math.cpp`)

Input and output

Strings and input

char can only hold a single letter/number,
but one way to hold multiple is a string

```
string str;  
cin >> str;
```

The above will only pull one word,
to get all words (until enter key) use:

```
getline(cin, str);    (See: stringInput.cpp)
```

More Output

When showing **doubles** with cout, you can change how they are shown

For example, to show a number as dollars and cents, you would type (before cout):

```
cout.setf(ios::fixed);  
cout.setf(ios::showpoint);  
cout.precision(2);
```

More Output

There are two ways to get output to move down a line: endl and “\n”

```
cout << endl;
```

... is the same as...

```
cout << “\n”
```

I will use both when coding

Madlibs

(see: `madlibs.cpp`)

bool

bool - either **true** or **false**

You have the common math comparisons:

> (greater than), e.g. $7 > 2.5$ is **true**

== (equals), e.g. $5 == 4$ is **false**

<= (less than or eq), e.g. $1 <= 1$ is **true**

If you cout this, “false” will be 0
and “true” will be 1 (anything non-zero is T)

Double trouble!

(See: `doubleCompare.cpp`)

Double trouble!

When comparing **doubles**, you should use `fabs` to see if relative error is small:

$\text{fabs}((x-y)/x) < 10\text{E}-10$

(**double** has about 16 digits of accuracy so you could go to $10\text{E}-15$ if you want)

For comparing Strings, use: (0 if same)
`string1.compare(string2)`
